**Multi Depot Vehicle Routing for inspection of Electric Grid substations
using MDVRP formulation and a hybrid genetic algorithm**

by

Dr. Spathis Vasileios

Electrical Engineer, Aristotles University of Thessaloniki

Submitted to fulfill part of
requirements for the acquisition of
Masters Degree
2015

Approved by the three members of the Commission of Inquiry:

Chief Examiner (Supervisor)	Dr Georgios Saharidis Assistant Professor in Operations Research Methods in Industrial Management Department of Mechanical Engineering, University of Thessaly
Second Examiner	Dr. George Liberopoulos Professor in Stochastic Methods in Production Management Department of Mechanical Engineering, University of Thessaly
Third Examiner	Dr. George Kozanidis Assistant Professor in Optimization Methods of Production/Service Systems Department of Mechanical Engineering, University of Thessaly

Acknowledgements

This project would not have been possible without the support of many people. Many thanks to my adviser, G. Saharidis, who read my numerous ideas and helped, make some sense of the confusion. Thanks to the Independent Power Transmission Operator for awarding me a full scholarship for attending this Master's Degree. Special thanks to my family and especially my wife for providing the necessary time and space for completing this dissertation. Special thanks to my parents, to my father and mother in law for their support and to numerous friends who endured this long process with me, always offering support and love.

Vasileios Spathis

Multi Depot Vehicle Routing for inspection of Electric Grid substations using MDVRP formulation and a hybrid genetic algorithm

VASILEIOS SPATHIS

University of Thessaly, Department of Mechanical Engineering, 2015

Supervisor: Dr. George Saharidis, Assistant Professor in Operations Research Methods in Industrial Management, Department of Mechanical Engineering, University of Thessaly

Abstract

The inspection of electric substations that support the electric grid, are a major part of the stability of the electric transmission system. This thesis addresses the routing of such inspections as an MDVRP problem. The proposed formulation is solved using optimization software. A hybrid genetic algorithm is also proposed that uses as initial population a set of feasible solution extracted from the optimization software. The proposed hybrid genetic algorithm performs well and managed almost at every scenario of initial population, to further optimize the objective produced from optimization software.

1. Literature Review

1.1. Introduction

A brief literature review is presented on optimization for vehicle route problems and multi depot vehicle route problems. Genetic algorithms regarding those problems will be discussed and certain aspects of the genetic evolution are displayed.

1.2. MDVRP

Many distribution systems widely depend on the routing and scheduling of vehicles through a set of customers requiring service. The Vehicle Routing Problem (VRP) is the designing of a group of minimum-cost vehicle routes, originating and terminating at a central depot, for a fleet of vehicles that services a set of customers with known demands. Each customer is serviced exactly once and, furthermore, all customers must be assigned to vehicles without exceeding vehicle capacities [1].

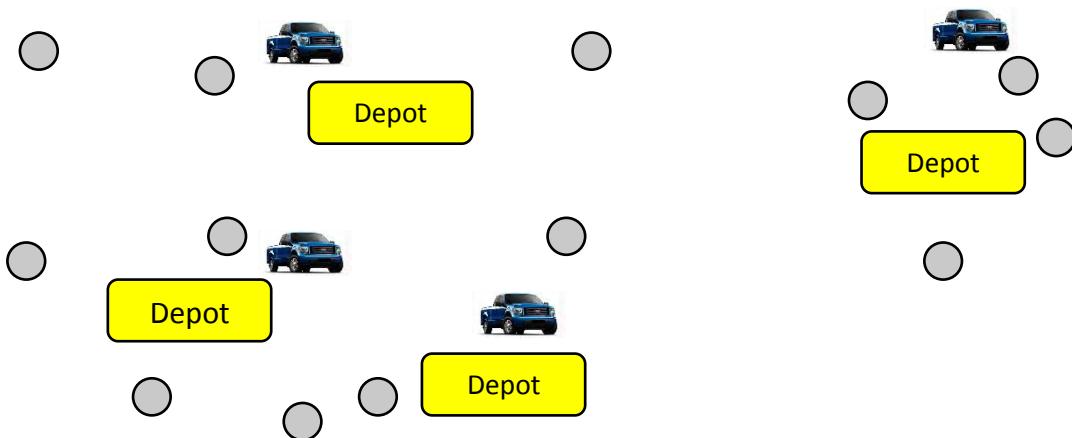

Figure 1: Multi depots and customers to be served

MDVRP (Multi Depot Vehicle Route Problem) on the other hand introduces several depots that are ready to serve customers, with only one to be assigned for every customer. Furthermore the rest of the restrictions of the general VRP problem are valid. Therefore, each customer is visited (serviced) once, each vehicle must leave and return to the same depot and the fleet size at each depot is specified. As expected, the objective function is on both occasions directly related to the total trip time, or distance, or fuel consumption of the set of trips that cover customer need.

The MDVRP is NP-hard [1] [2] therefore analytic solution is only available for a small set of customers and depots. The development of heuristic algorithms for this problem class is of primary interest.

1.3. Research on VRP and MDVRP

There has been a generous list of papers introducing several aspects on VRP and MDVRP. Several papers introduce extensions on VRP such as time windows, backhauls, pickup and delivery VRP etc.

Exact algorithms were proven to be time consuming and hardly ever applicable Liong et al. [3]. Therefore, heuristics are usually more applicable on realistic problems.

The oldest heuristic on MDVRP was developed by Tillman and Cain [4] and Wren and Holliday [5]. Tillman and Cain introduced a heuristic based on the saving algorithm of Clark and Wright [6] which implies that every combination of routes is resulting to cost saving. In this heuristic, as many other heuristic developed at this early stage, the improvement stage of the initial solution was missing resulting to a poor optimization overall. Whereas the latter group (Wren and Holliday) introduced a heuristic of two stages in which a feasible solution is obtained in the first stage and an improvement of this feasible solution is calculated in the second stage. This procedure of obtaining an initial solution first and then improving it is one of the two common structures of the heuristics developed to solve the MDVRP [7].

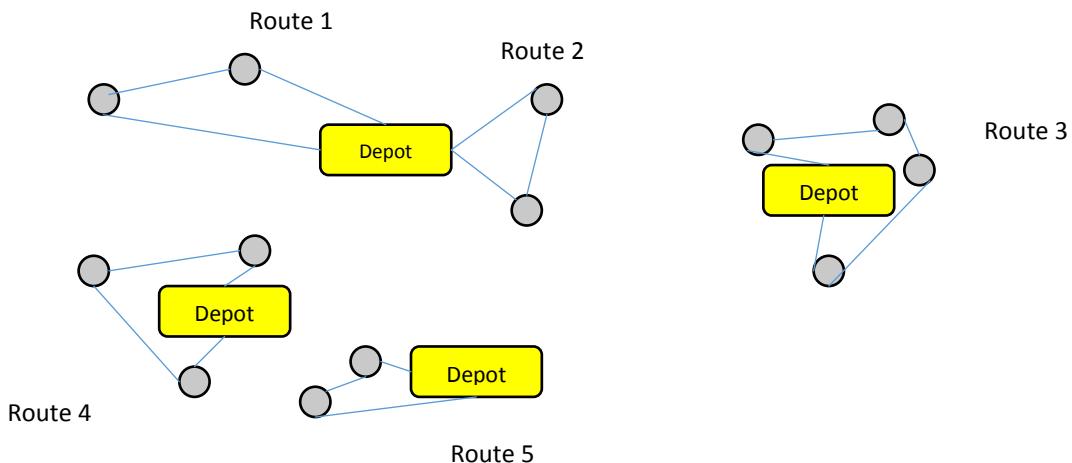

Figure 2: A feasible routing solution

The second well known structure involves decomposing the MDVRP into sub problems first and then solving these sub problems separately before connecting them iteratively. Golden et al. [8] in 1977 developed an algorithm using the cluster first - route second principle. This algorithm clusters customers in the first stage according to the distances to the depots closest and second closest to the customers. A few years later Raft [9] developed an algorithm for which the problem is decomposed in five, instead of two, stages. The five stages are solved separately and then connected iteratively.

Chao et al. [10] applied the cluster first - route second principle presented by Golden et al. [11] to obtain an initial solution and improve this solution by changing the depot assignments of the customers. Hence, they combine the two commonly applied structures in heuristics solving the MDVRP. In the improvement procedure, Chao et al. [10] applied the record-to-record approach [12].

Tabu search algorithms on the MDVRP have been first introduced by Renaud et al. [13] and Cordeau et al. [14]. These algorithms use memory structures to memorize the examined

solutions. A tabu search algorithm will not examine a solution more than once as it marks the visited solutions as tabu in its memory for a certain number of iterations [15].

The years after 2000, research has primarily been dedicated to extensions of the MDVRP but the classical MDVRP has been investigated as well. Pisinger and Ropke [16] developed a unified heuristic to solve five extensions of the classical VRP including the MDVRP. This heuristic uses the adaptive large neighborhood search framework designed by (Ropke and Pisinger, 2006 [17]). This framework expands and contracts the search for a better solution by choosing adaptively among a number of heuristics that are able to insert and remove customers in a route.

Ho et al. [7] were the first to propose two hybrid genetic algorithms to solve the MDVRP. The first algorithm generates the initial population randomly while the second algorithm uses the savings algorithm and the nearest neighbor heuristic. The nearest neighbor heuristic is a routing heuristic that solves the TSP. It searches for the nearest unvisited customer location until every location is visited and then returns to the starting location. Mirabi et al. [18] presented three hybrid heuristics to solve the MDVRP where these heuristics combine components from constructive heuristic search and improvement methods. With constructive heuristic search a complete solution, i.e. all customers satisfied, is 'constructed' by extending an empty solution.

Vidal et al. [19] introduced another heuristic which is a hybrid genetic algorithm. This so called Hybrid Genetic Search with Adaptive Diversity Control (HGSADC) addresses three extensions of the VRP including the MDVRP. Vidal et al. apply the giant-tour representation and the Split algorithm as Prins [20] did to obtain a routing scheme corresponding to the randomly determined assignment scheme. The giant-tour representation implies that from each depot one route starts, serving all customers assigned to that depot and then returns to the depot. The Split algorithm is used to find the optimal segmentation of the giant-tour into separate routes. One of the differences between regular genetic algorithms and the algorithm developed by Vidal et al. is the control on the diversity of the population. Vidal et al. do not include a mutation phase, instead they apply "advanced population diversity management schemes" of including feasible as well as infeasible solutions and refreshing the population when a pre-specified maximum number of iterations made without improving the best solution obtained so far is reached. Also, a diversity contribution is included in the fitness measure used to evaluate the chromosomes. This enhances the evolution of the population while avoiding it to converge prematurely.

Another difference is the inclusion of an education phase to further enhance the improvement of chromosomes. In this phase local-search procedures educate the chromosomes by improving their routing schemes.

Vidal et al. demonstrated that their algorithm is the best performing method to approach the MDVRP.

1.4. Genetic Algorithms

Genetic algorithms (GA) is a subset of evolutionary algorithms and are adaptive, heuristic and mimic natural evolution described by Darwin. This heuristic (also sometimes called a metaheuristic) is routinely used to generate useful solutions to optimization and search problems. Genetic algorithms generate solutions to optimization problems using techniques inspired by natural evolution, such as inheritance, mutation, selection, and crossover.

In a genetic algorithm, a population of candidate solutions (called individuals, creatures, or phenotypes) to an optimization problem is evolved toward better solutions. Each candidate

solution has a set of properties (its chromosomes or genotype) which can be mutated and altered; traditionally, solutions are represented in binary as strings of 0s and 1s, but other encodings are also possible.

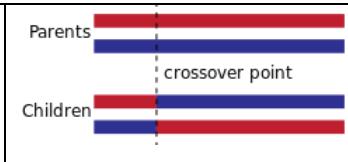

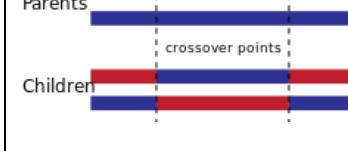

The evolution usually starts from a population of randomly generated individuals, and is an iterative process, with the population in each iteration called a generation. In each generation, the fitness of every individual in the population is evaluated; the fitness is usually the value of the objective function in the optimization problem being solved. The more fit individuals are stochastically selected from the current population, and each individual's genome is modified (recombined and possibly randomly mutated) to form a new generation. The new generation of candidate solutions is then used in the next iteration of the algorithm. Commonly, the algorithm terminates when either a maximum number of generations has been produced, or a satisfactory fitness level has been reached for the population. [21]

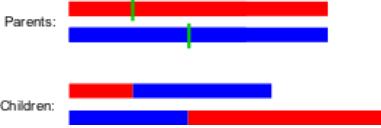

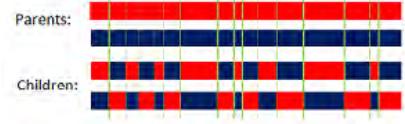

A typical genetic algorithm requires a genetic representation of the solution domain and a fitness function to evaluate the solution domain.

A standard representation of each candidate solution is as an array of bits. Arrays of other types and structures can be used in essentially the same way. The main property that makes these genetic representations convenient is that their parts are easily aligned due to their fixed size, which facilitates simple crossover operations. Variable length representations may also be used, but crossover implementation is more complex in this case. Tree-like representations are explored in genetic programming and graph-form representations are explored in evolutionary programming; a mix of both linear chromosomes and trees is explored in gene expression programming. Once the genetic representation and the fitness function are defined, a GA proceeds to initialize a population of solutions and then to improve it through repetitive application of the mutation, crossover, inversion and selection operators.

1.4.1. Crossover

Crossover as mentioned above is a genetic operator used to vary the programming of a chromosome or chromosomes from one generation to the next. It is analogous to reproduction and biological crossover, upon which genetic algorithms are based. Cross over is a process of taking more than one parent solutions and producing a child solution from them. There are methods for selection of the chromosomes which include the Fitness proportionate selection, also known as fitness proportionate selection where the probability of an individual to be selected is proportional of the fitness value, the Boltzmann selection, the Tournament selection, the Rank selection, the Steady state selection and the Local selection method.

One Point Crossover	 Parents: Red bar, Blue bar	A single crossover point on both parents' organism strings is selected. All data beyond that point in either organism string is swapped between the two parent organisms.
Two Point Crossover	 Parents: Red bar, Blue bar	Two-point crossover calls for two points to be selected on the parent organism strings. Everything between the two points is swapped between the parent organisms, rendering two child organisms

Cut and Splice	 Parents: [Red, Blue]	Another crossover variant, the "cut and splice" approach, results in a change in length of the children strings. The reason for this difference is that each parent string has a separate choice of crossover point.
Uniform Crossover and half Uniform Crossover	 Parents: [Red, Blue]	The Uniform Crossover uses a fixed mixing ratio between two parents. Unlike one- and two-point crossover, the Uniform Crossover enables the parent chromosomes to contribute the gene level rather than the segment level.

After a selection method is applied the selected chromosomes are combined in order to produce their children. Combination methods include One point crossover, two point crossover and cut and splice crossover as described on the table below:

A special category of crossover techniques apply to ordered chromosomes, when the representation implies a certain order at the chromosome and therefore the children produced need to apply to the same rules.

One such case is when the chromosome is an ordered list, such as an ordered list of the cities to be travelled for the traveling salesman problem. There are many crossover methods for ordered chromosomes. However, sometimes a crossover of chromosomes produces conjunctions which violate the constraint of ordering and thus need to be repaired.

1. Partially matched crossover (PMX): In this method, two crossover points are selected at random and PMX proceeds by position wise exchanges. The two crossover points give matching selection. It affects cross by position-by-position exchange operations. In this method parents are mapped to each other, hence we can also call it partially mapped crossover [22]
2. Cycle crossover (CX): Beginning at any gene i in parent 1, the i -th gene in parent 2 becomes replaced by it. The same is repeated for the displaced gene until the gene which is equal to the first inserted gene becomes replaced (cycle).
3. Order crossover operator (OX1): A portion of one parent is mapped to a portion of the other parent. From the replaced portion on, the rest is filled up by the remaining genes, where already present genes are omitted and the order is preserved.
4. order-based crossover operator (OX2)
5. position-based crossover operator (POS)
6. voting recombination crossover operator (VR)
7. alternating-position crossover operator (AP)
8. sequential constructive crossover operator (SCX)[6]

1.4.2. Mutation

Mutation is a genetic operator used to maintain genetic diversity from one generation of a population of genetic algorithm chromosomes to the next. It is analogous to biological mutation. Mutation alters one or more gene values in a chromosome from its initial state. In mutation, the solution may change entirely from the previous solution. Hence GA can come to better solution by using mutation. Mutation occurs during evolution according to a user-definable mutation

probability. This probability should be set low. If it is set too high, the search will turn into a primitive random search.

The classic example of a mutation operator involves a probability that an arbitrary bit in a genetic sequence will be changed from its original state. A common method of implementing the mutation operator involves generating a random variable for each bit in a sequence. This random variable tells whether or not a particular bit will be modified. This mutation procedure, based on the biological point mutation, is called single point mutation. Other types are inversion and floating point mutation. When the gene encoding is restrictive as in permutation problems, mutations are swaps, inversions and scrambles.

The purpose of mutation in GAs is preserving and introducing diversity. Mutation should allow the algorithm to avoid local minima by preventing the population of chromosomes from becoming too similar to each other, thus slowing or even stopping evolution. This reasoning also explains the fact that most GA systems avoid only taking the fittest of the population in generating the next but rather a random (or semi-random) selection with a weighting toward those that are fitter. [23]

Different mutation types are introduced:

- Bit string mutation

The mutation of bit strings ensue through bit flips at random positions.

Example:

```
1 0 1 0 0 1 0
↓
1 0 1 0 1 1 0
```

The probability of a mutation of a bit is $1/\lambda$, where λ is the length of the binary vector. Thus, a mutation rate of 1 per mutation and individual selected for mutation is reached.

- Flip Bit

This mutation operator takes the chosen genome and inverts the bits (i.e. if the genome bit is 1, it is changed to 0 and vice versa).

- Boundary

This mutation operator replaces the genome with either lower or upper bound randomly. This can be used for integer and float genes.

- Non-Uniform

The probability that amount of mutation will go to 0 with the next generation is increased by using non-uniform mutation operator. It keeps the population from stagnating in the early stages of the evolution. It tunes solution in later stages of evolution. This mutation operator can only be used for integer and float genes.

- Uniform

This operator replaces the value of the chosen gene with a uniform random value selected between the user-specified upper and lower bounds for that gene. This mutation operator can only be used for integer and float genes.

- Gaussian

This operator adds a unit Gaussian distributed random value to the chosen gene. If it falls outside of the user-specified lower or upper bounds for that gene, the new gene value is clipped. This mutation operator can only be used for integer and float genes.

1.5. Conclusion

A brief literature review on research papers regarding the VRP and MDVRP problems were presented. Also the genetic algorithms on vehicle routing problems were discussed. In particular the different processes in a genetic algorithm were introduced and small examples were given. The next Chapter will discuss the problem that is challenged and the parameters that define it.

2. Problem Description - Inspection of substations

2.1. Introduction

In this Chapter we will discuss the importance of the good working conditions of the transmission grid of a country and the substations between. A working real model of such a system is the set of substations that cover central Greece. This system is presented and the different aspects of the human inspections are introduced.

2.1.1. General description of the Energy backbone

Customers of electric companies worldwide are convinced that electricity is there every second of the day ready to be used. What is not generally known is that electricity is actually made available as soon as someone chooses to consume. Electric power that runs through the transmission lines is produced for every customer at the moment he switches on an electric appliance.

This small detail of the electric energy makes the reliable transmission of power a very important stage of the chain that connects production and consumption. Transmission of energy must be available 24/7 and cannot be interrupted at any point. If an interruption is to be made or happens accidentally (for example a failure of a transmission line) then an adequate number of alternative transmission routes must be available. Luck of backup routes is a major reason for a massive power cut.

Electric-power transmission is the bulk transfer of electrical energy, from generating power plants to electrical substations located near demand centers. This is distinct from the local wiring between high-voltage substations and customers, which is typically referred to as electric power distribution. Transmission lines, when interconnected with each other, become transmission networks. The combined transmission and distribution network is known as the "power grid".

A transmission line as the one shown on the right connects to substations. A substation is a part of an electrical generation, transmission, and distribution system. Inside a substations voltage is transformed from higher level to lower level, or the reverse, or several other important functions regarding the quality of the voltage and the protection of the system are performed. Between the generating station and consumer, electric power may flow through several substations at different voltage levels.

Figure 3: A transmission line

Generally, substations are unattended, relying on SCADA for remote supervision and control. Through the SCADA the control center of the transmission company can monitor several aspects of the process, and can interfere if necessary to recover part of a failed circuit.

A substation may include transformers to change voltage levels between high transmission voltages and lower distribution voltages, or at the interconnection of two different transmission voltages. The word substation comes from the days before the distribution system became a grid. As central generation stations became larger, smaller generating plants were converted to distribution stations, receiving their energy supply from a larger plant instead of using their own

generators. The first substations were connected to only one power station, where the generators were housed, and were subsidiaries of that power station.

2.1.2. Importance of substations

As mentioned above. Substations are unattended and rely on remote supervision and control software. Nevertheless, the human inspection of the substation is been considered as a major part of the maintenance process.

Substations are considered as the interconnection part of the transmission lines grid (the ultra-high and high voltage grid) and the distribution grid (the middle and low voltage grid). The transformation of power to lower or higher voltage and the automated control and protection processes realized in a substation must be also 24/7 available.

2.1.3. Inspection

Human inspection of this kind of infrastructure is essential part of the process. Every transmission company that operates transmission lines grid is using human inspection for maintenance purposes. Highly trained inspectors visit substations every a few days (regularly twice a month is considered as a good balance of cost and effectiveness) and run a certain list of routine checks in the substation. For instance a simple walk nearby the transformers in order to hear the noise or to observe leaks, would provide important information that cannot be read to any characteristic obtained through the SCADA software until maybe it's too late.

Regularly the results of such an inspection is been handed to the technical personnel who will take immediate actions such as an extraordinary service or replacement of fault equipment, or rescheduling of the planned service of equipment involved.

The above action will actually prevent a major fault to the system and help to preserve the availability of the electric power as promised by the electric company to the final customer.

A regular human inspection of every substation is a time consuming process due to the placement of the substations. The substations are sporadically built in a large area. Typically substations are 10 to 50 km from each other, and an area of 15.000 km² would have 30 to 50 substations. Greece for example has 331 substations that cover an area of 131.000 km². A map of substations that support Central Greece is shown on the right.

One the other hand the inspectors are usually stationed in certain locations. For example, for the stations of Central Greece, inspectors are located at 4 spots, considered as "depots". Every route of inspection is commencing at a depot, runs through several substations and is finished at the same depot.

Figure 4: A substation

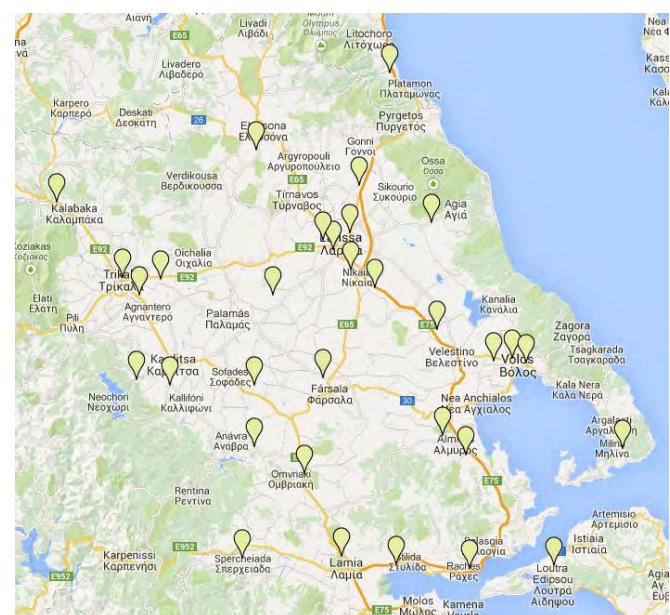

Figure 5: The substations of Central Greece

At each substation the inspector is spending an amount of time usually depending on the size of the substation and the irregularity of the equipment stationed at the site. This amount of time can be estimated for every substation beforehand.

Furthermore, each route of inspection cannot exceed a certain time. It has been proven from experience, and it can be assumed as common sense that after a few inspections on the same day, the inspector is “losing interest” due to fatigue and routine.

Lastly, the inspection needed of the next month is determined at the last week of the running month. Although that someone could assume that the visits are definite, the experience has proven otherwise. For example, the inspection of a substation at the first two weeks of December can be excluded if a major part of the substation will be visited by technical teams for a scheduled maintenance. At that day several experts will visit the substation and will be able to inspect thoroughly the equipment and the substation field; therefore the regular inspection can be excluded from the scheduling. While this seems like a little gain for the inspection program, if we take into account that every two weeks 5% to 10% of the substations will be visited by maintenance teams, we can imagine that the scheduled inspection program can be dramatically reduced.

This thesis will address the problem of inspection of substation using a general multi depot vehicle routing algorithm and hybrid genetic algorithms. At the final stage a path of solutions will be suggested. The algorithm will be tested at several scenarios of substations.

2.2. Conclusion

At this Chapter the problem of the human inspection of the scattered electric substations is presented. This is a MDVRP problem with many particularities. The importance of the uninterrupted energy transfer and transformation was also emphasized. Lastly, parameters of the solutions and certain logical restriction were introduced. At the next Chapter the mathematical formulation of the problem is presented.

3. Problem formulation

3.1. Introduction

The mathematical formulation used to address this MDVRP problem depends on the work of Dondo et al. [24] regarding a time window multi depot vehicle routing problem. This generic formulation was adapted to the inspection routing problem. The formulation is presented and explained thoroughly.

3.2. Indices and sets of the problem

The sets created and the corresponding indices used for the formulation are displayed at the Table 1 on the right.

The “cost” travelling from a substation or depot to another substation or depot is considered not the km between them but the time needed for travelling. This was

s,k	Substations
d	Depots
t	Days for routing

TABLE 2: INDICES USED TO FORMULATE THE PROBLEM

S={1,2,...,n}	Substations
D={1,2,...,m}	Depots
A(s,k)	Time between s and k, where s,k $\in \{S \cap D\}$
T={1,2,...,d}	Days for inspection

TABLE 2: SETS OF THE PROBLEM

chosen because of another aspect of the problem which is the time to be consumed at each substation, since these two parameters will determine the total cost.

3.3. Parameters

The known data of the problem are:

- c_{sk} Time to travel between s and k substation (or depot) in minutes
- m_s Time that is spent to inspect the s substation in minutes
- MT Maximum time of a route (including travelling and inspecting time)

3.4. Variables

At the Table 3 below there is a list of the variables used. The cost of every route is built as we visit the next substation.

Variable	Type of Variable	Variable descriptions
CV_s	Integer	Cumulative cost of a route until s substation
X_{st}	Binary	1 if s substation is visited at t day, 0

		otherwise
Y_{sd}	Binary	1 if s substation is visited from a route beginning at d depot, 0 otherwise
R_{sk}	Binary	1 if s substation is visited before k substation, 0 otherwise
CVT_{dt}	Integer	Total cumulative cost of t day route beginning from d depot

TABLE 3: THE VARIABLES OF THE PROBLEM

The last variable makes the objective function very simple and straightforward. We want to minimize the sum of all the routes that serve the substations that take place any of the t days and start from any of the d depots. Therefore:

$$\min \sum_{d,t} CVT_{dt}$$

Subject to:

1. $\sum_{d \in D} Y_{sd} = 1, \forall s \in S$
2. $\sum_{t \in T} X_{st} = 1, \forall s \in S$
3. $CV_s \geq (c_{ds} + m_s)(X_{st} + Y_{sd} - 1), \forall s \in S, d \in D, t \in T$
4. $CV_k \geq CV_s + (c_{sk} + m_k) - M(1 - R_{sk}) - M(2 - X_{st} - X_{kt})$
5. $CV_s \geq CV_k + (c_{sk} + m_s) - MR_{sk} - M(2 - X_{st} - X_{kt}), \forall s, k \in S, t \in T, s < k$
6. $CVT_{dt} \geq CV_s + c_{sd} - M(2 - X_{st} - Y_{sd}), \forall s \in S, d \in D, t \in T$
7. $CVT_{dt} \leq MT, \forall d \in D, t \in T$

where M is a big number. The restrictions above make determine the feasibility of the solution as follows:

1. Each substation is assigned to one and only depot. This restriction arises from the description of the problem since we want the inspector to depart from one depot visit a number of substations and return to the same depot. We describe this restriction as a summation of all y_{sd} binary variables for all d depots for each s substation to be equal to 1. This restriction will be expanded to $k=\max(s)$ restrictions (as many as the substations).
2. Each substation is served (visited) only once. This restriction is also defined by the problem description. The restriction is a summation of all x_{st} binary variables for all t days (t can be also assumed as routes of inspections) for each s substation to be also equal to 1. Therefore for each substation s only one x_{st} will be equal to 1. This restriction will also is
3. The accumulated time of a route until the s substation is the sum of the time to travel from a depot to the substation s (parameter: c_{sk}) and the time needed to inspect the substation (parameter: m_s), taking in advance that s is the first substation in the route. This restriction applies only for the first substations for every route and can provide $s \times d \times t$ restrictions. Most of them will be neglected as only one substation for every route will be the first.
4. The accumulated time of a route when k substation is visited is the sum of the accumulated time until s substation (variable CV_s), the time travelling from s to k substation (parameter: c_{sk}) and the time to inspect k substation (parameter: m_k). All these are taking into consideration if s substation is visited before k and if s and k substation are visited the same date (t). This restriction will be expanded to $s \times d \times t$ restrictions.
5. This restriction is complementary to the last one with respect of k been visited before s.
6. The total accumulated time of the route is when the route is arriving at depot, and therefore the accumulated time until the s substation (variable: CV_s) is summed to the time needed to travel from s substation to d depot. This is controlled by the binary variables determining if s is visited at t day and if s substation is assigned to d depot. This restriction is expanded to $s \times d \times t$ restrictions
7. This restricts the total amount of traveling time of every route. The restriction is expanded to d formulas.

The formulation at Dondo paper was applied here, eliminating the time window restrictions but using the time indices as routing indices. Therefore from every depot we can have several routes, one per day. This can also be used in order to restrict the number of routes but it was irrelevant to the solution needed and therefore it was ignored. The total number of restriction is added to:

$$4(s \cdot d \cdot t) + 2 \cdot s + d$$

Therefore for a standard problem of 24 substations, 4 depots and 12 days to visit we could have 4660 restriction.

3.5. Conclusion

The mathematical formulation of the MDVRP problem regarding the inspection of the electric substations was presented. The formulation is a customization of Dondo work on time window MDVRP problem. Next Chapter the methods used to solve the problem are introduced.

4. Methods used for solution

4.1. Introduction

The MDVRP problem of the inspection of electric grid substations was solved using two different methods presented in this Chapter. Firstly the mathematical formulation was written in C++ and fed to CPLEX optimization studio. Since the problem is NP-hard the solution beyond a threshold is not expected at logical time limitations.

Furthermore a genetic algorithm also presented below, was written in C++ and run in order to find feasible solutions. The genetic algorithm is doing all the basic processes adjusted to a MDVRP problem.

4.2. Running standard optimization in CPLEX

The ILOG CPLEX Optimization Studio was used for the calculation of the analytic solutions. The code producing the input to the CPLEX studio was written in C++ and is included at Appendix 8.3. The code uses two input files for the data. The first file contains the distance matrix of every depot and substation to each other as shown at Appendix 8.4. The instance shown there is the first scenario that was optimized at CPLEX and hybrid genetic algorithm, and is also the real scenario of the substation at Central Greece. All other scenarios are a random simulation of points. The second file is a file that we determine the amount of time the inspector will spent at each substation.

The parameters and limitations that were used for the simulation were 24 substation, 4 depots and 360min max route time. These parameters and limitations were introduced due to the fact that they are the actual facts of the problem regarding the inspection of substations of Central Greece. Execution of the Code with CPLEX return the output attached at Appendix 8.7.

The solutions were saved as a list of the variables of the problem, and the real routes can be extracted from those values. For example a feasible solution can be extracted from the variables shown below:

Solution 180 with objective 2050

CVTdt(0,5)=328

CVTdt(0,7)=359

CVTdt(1,0)=239

CVTdt(1,4)=268

CVTdt(2,1)=251

CVTdt(2,6)=280

CVTdt(3,8)=325

At this part of the solution the total objective is shown as well as the total cost of each route from every deposit. For instance an inspection route proposed from deposit 0 as route 5 is 328 minutes long.

Xst(0,5)=1

Xst(1,5)=1

Xst(2,7)=1

Xst(3,7)=1

Xst(4,5)=1

Xst(5,5)=1

Xst(6,7)=1

Xst(7,4)=1

Xst(8,0)=1

Xst(9,4)=1

The x_{st} variable if 1, defines that s substation will be visited at t route. For instance substation 0 will be visited at 5th route, as well as substation 1, 4, 5. This information alone is not conclusive of the exact route proposed.

```
Xst(10,0)=1
Xst(11,4)=1
Xst(12,4)=1
Xst(13,1)=1
Xst(14,1)=1
Xst(15,1)=1
Xst(16,6)=1
Xst(17,6)=1
Xst(18,8)=1
Xst(19,8)=1
Xst(20,8)=1
Xst(21,8)=1
Xst(22,7)=1
Xst(23,6)=1
```

Ysd(0,0)=1
Ysd(1,0)=1
Ysd(2,0)=1
Ysd(3,0)=1
Ysd(4,0)=1
Ysd(5,0)=1
Ysd(6,0)=1
Ysd(7,1)=1
Ysd(8,1)=1
Ysd(9,1)=1
Ysd(10,1)=1
Ysd(11,1)=1
Ysd(12,1)=1
Ysd(13,2)=1
Ysd(14,2)=1
Ysd(15,2)=1
Ysd(16,2)=1
Ysd(17,2)=1
Ysd(18,2)=1
Ysd(19,3)=1
Ysd(20,3)=1
Ysd(21,3)=1
Ysd(22,0)=1
Ysd(23,2)=1

The y_{sd} variable if 1, determines that s substation is assigned to d depot. Therefore substation 0,1,2,3,4,5,6,22 are assigned at depot 0. Taking into account that 0,1,4,5 substations are visited at 5th route, we can safely conclude that a route visiting this substation has been proposed by the optimization.

CVs(0)=143
CVs(1)=64
CVs(2)=40
CVs(3)=231
CVs(4)=190
CVs(5)=274
CVs(6)=109
CVs(7)=106
CVs(8)=59
CVs(9)=53
CVs(10)=177
CVs(11)=169
CVs(12)=227
CVs(13)=77
CVs(14)=141
CVs(15)=217
CVs(16)=69
CVs(17)=141
CVs(18)=85
CVs(19)=166
CVs(20)=239

The accumulated cost is shown for every substation. Please note the accumulated cost for substations 0,1,4,5 highlighted. The cost is building up as the substations are visited. Therefore substation 1 must be the first visited as the cost until 1 is the lowest. Then substation 0 and 4 and lastly 5. The return to depot is not shown since the arriving at the depot builds the total accumulated cost shown above.

$CVs(21)=301$
$CVs(22)=326$
$CVs(23)=225$

The cost of the routes as is built is shown at the graph below:

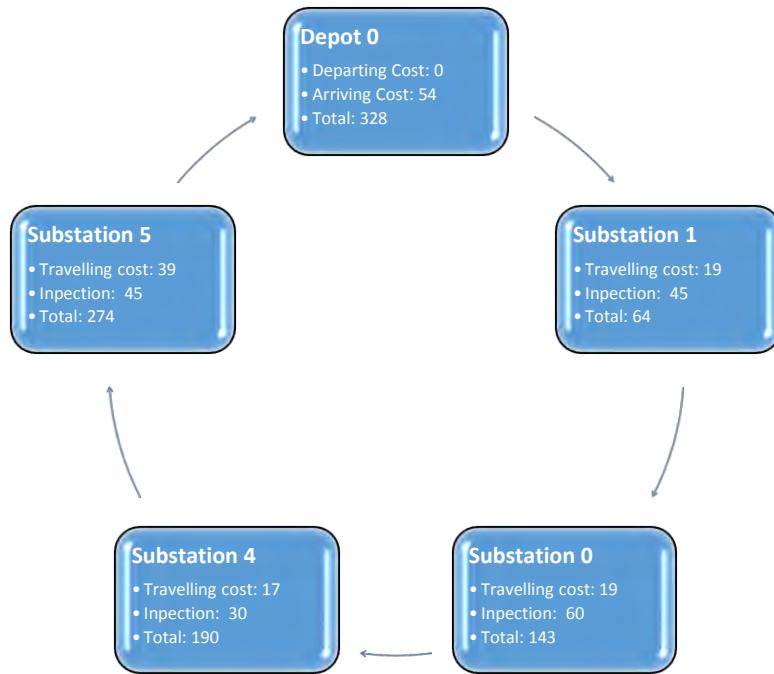

Figure 6: The calculation of cost

The departing cost from the Depot 0 is zero, and the travelling cost to the first substation of the route is 19. The inspection of the substation is 45 minutes long and therefore the accumulated cost until substation one is 64 minutes. The route is then travelling with 19min cost to substation 0, and after the inspection time of this substation (60min) the total cost is 143. Then substation 4 is visited after travelling for 17min and the accumulated cost is 190 including the inspection cost. Lastly, substation 5 is visited and then the route is ending at Depot 0 with a total cost of 328 min.

The route proposed on the map is included below:

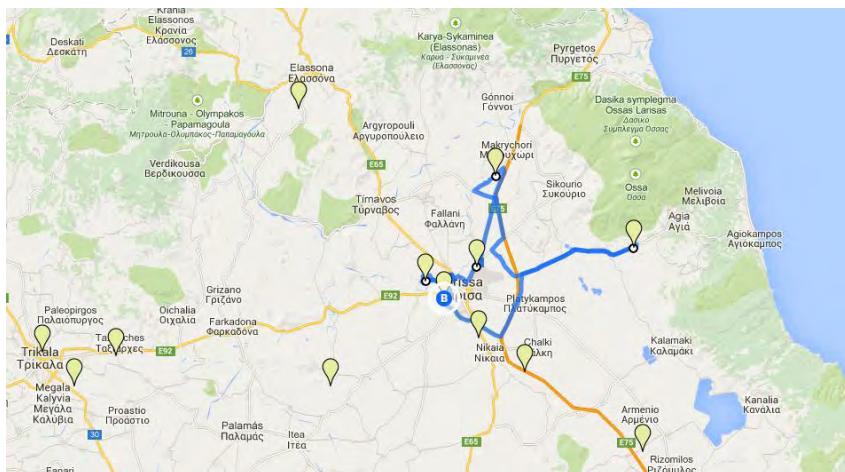

Figure 7: A feasible route

The code was run 10 times. The scenario 0 is the actual scenario with the real distances of the substations. The other 9 scenario were built with pseudorandom process. The number of substations and depots and the restrictions of max route length (in time), were kept constant at all scenarios that were solved.

4.3. The Genetic Algorithm

A genetic algorithm was developed to be tested at the same scenarios and to check its usefulness. The code is attached at Appendix 8.6 and was written in C++.

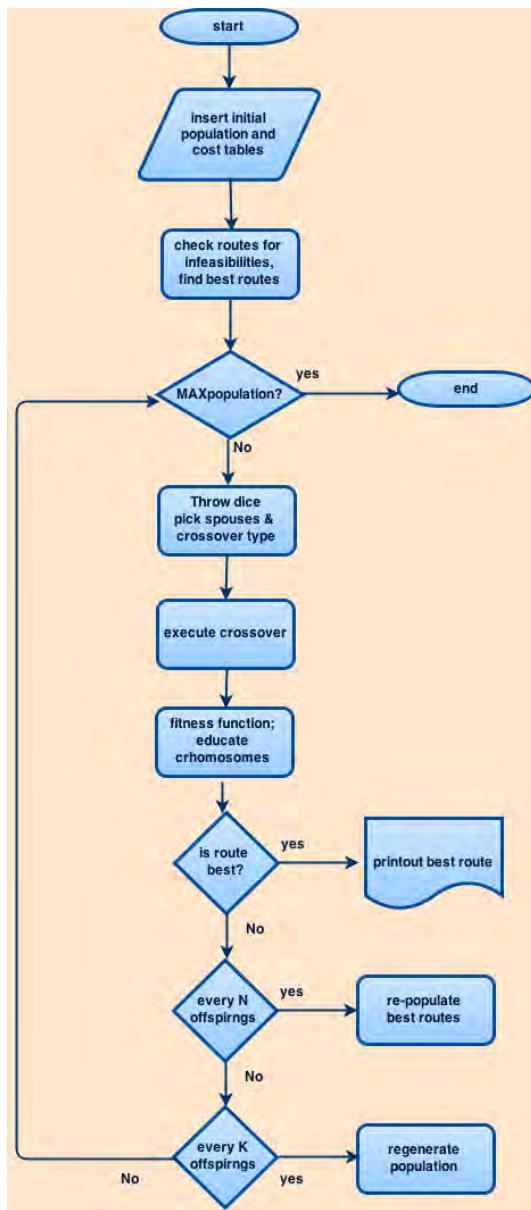

Figure 8: The genetic algorithm

The general purpose of the code was not to produce an initial population as a generic genetic algorithm. The genetic algorithm uses initial solutions as chromosomes that are introduced by the user. For this purpose for each of the produced scenarios from CPLEX the solution pool of CPLEX was used. The solution pool is a set of feasible solutions that CPLEX algorithm is finding in the way to the optimization algorithm. Those solutions were mined from CPLEX and then fed to the

genetic algorithm. The format of the chromosomes is displayed in Appendix 8.5 and sample is shown below.

Chromosome 1
100 0 100 100 4 5 6 100 100 1 3 22 2 100 101 9 101 101 101 8 101 101 7 12 11 101 101 10 101 102 13 14 15 102 102 16 17 18 23 102 103 19 20 21 103

The chromosome is built by routes. For the chromosome above, each three-digit of 100 or more is a depot, were each two-digit number is a substation. Each chromosome is a feasible solution. The chromosome above represents 10 routes that will visit all substations. For instance the first route will depart from depot 0 (represented with number 100) will visit substation 0 and return to depot 0.

For each chromosome that is inserted to the code or produced by the code a simple clever education is executed. This education is the simple sorting of the algorithms routes (genes) that are combined into a feasible solution in order to make it more efficient. For example for the above chromosome that is inserted at the initial population all different rerouting inside every gene are tested in order to find a near better solution. Therefore for route 100->4->5->6->100 proposed by the solution pool of CPLEX every other routing will be tested and evaluated. For every better routing than the initial a chromosome will be added at the population. Therefore route 100->5->6->5->100 and route 100->5->4->6->100 and all other routes will be evaluated in terms of minutes and if found better than the proposed then a total feasible solution (chromosome) will be created which will include the new gene and this chromosome is attached at the initial population list.

The genetic algorithm then introduces by means of randomness three different crossover-processes or a mutation process. Crossover process as introduced in genetic algorithms for VRP optimization is a rather impotent procedure. The genes that are taken from two chromosomes are combined with various ways but highly chances are that the chromosome produced will be non-feasible solution. The proof of that is shown below:

Let for instance get two chromosomes:

Chromosome 1
100 0 100 100 5 6 100 100 1 22 3 2 100 100 4 100 101 10 101 101 101 9 8 7 12 11 101 102 13 14 15 102 102 16 17 18 23 102 103 19 103 103 20 21 103
Chromosome 2
100 0 2 100 100 5 1 100 100 3 4 6 7 100 101 10 101 101 13 14 16 101 101 9 8 11 12 101 102 23 15 102 102 17 102 103 21 19 22 103 103 20 18 103

Now by random lets combine them in order to produce two offsprings:

Chromosome Offspring 1
100 0 100 100 5 6 100 100 1 22 3 2 100 100 4 100 101 10 101 101 101 9 8 7 12 11 101 102 23 15 102 102 17 102 103 21 19 22 103 103 20 18 103
Chromosome Offspring 2
100 0 2 100 100 5 1 100 100 3 4 6 7 100 101 10 101 101 9 8 7 12 11 101 102 13 14 15 102 102 16 17 18 23 102 103 19 103 103 20 21 103

From chromosome offspring one 13, 14 and 16 substations are missing while 22 is visited twice. Similarly from chromosome two, substation 22 is also missing. Both chromosomes that were produced by random crossover process are not valid solution. Several papers suggested the

“fixing” procedure of the new chromosomes by neglecting one of the duals and inserting randomly or by a clever algorithm the missing nodes.

After the insertion process of the genes and the loading of the cost tables of the specific scenario, an evaluation of all genes is introduced. The “fitness process” as called is checking every chromosome and is evaluating the objective value. This value is stored with the chromosome, as part of its id.

Then a check of infeasible solution is taken place. This was introduced in order to clarify that the initial population includes only feasible solutions. Furthermore a function is called that populates an array with the chromosomes that scored the best objective value.

Following the initial procedures of the genetic algorithm there is the reproduction loop. Two randomly chosen chromosomes either from the general population or from the population of the best chromosomes are picked. Then with an intelligent random procedure the type of the crossover is chosen. This procedure in order to randomly pick a type of crossover function examines the length of the chromosome. Beside the objective function which is an accurate representation of the quality of the solution, the length of the chromosome is a strong indication of the maturity of the feasible solution. It can be easily understood that the optimized solution will have one of the shortest length, since the nodes will be swiftly combined in order to achieve the longest feasible routes that meet the restrictions and minimize the total cost.

The longer the chromosome, the more routes are included, each one starting and ending at a depot. For example an immature solution would be to have as many routes as nodes. Every route would start from a depot, visit only one substation and finish at the depot. The chromosomes that would describe such a solution would be quite long.

Immature chromosome 100 0 100 100 1 100 100 2 100 100 3 100 100 4 100 100 5 100 e.t.c
--

At those chromosomes the genetic algorithm is working on feasible conjunctions of routes by joining two routes that belong to the same depot, in order to produce a new and hopefully better route that will cover more nodes. The routes that are produced are instantly checked for feasibility (the fitness function) and if valid, they are added to the population.

If the chromosomes are quite short then the routes that are included cover cleverly the nodes. At this point the genetic algorithm is breaking randomly routes in order to produce a more primitive feasible solution. The purpose of this action is to regenerate a simpler and less robust solution that will then be the new raw material for the genetic evolution.

The mutation process combines two different feasible solutions and randomly exchanges the position of two genes in order to produce new chromosomes. If the new chromosomes are feasible and valid then they are added to the population.

The above process can be regarded as simple and trustworthy with minimum CPU surcharge that both optimizes and regenerates the population.

The new chromosomes as well as the chromosomes of the initial population are cleverly educated in order to improve their fitness performance. This procedure is successful generates new solutions that are also added to the population.

Several other procedure were written in order to clean the population from twins, display routes for debugging purposes, etc.

Lastly a procedure that generates an array with the best feasible solution is called every K^{th} generations. This procedure checks the population and locates the m better unique solutions. This population is preferable used from the genetic algorithm as propagating material, according to a random variable uniformly distributed. Another procedure is called every M^{th} generations in order to remove chromosomes (twins, worst scored etc) and regenerate the population.

The genetic algorithm was starting with the initial population fed by the solution pool of CPLEX and run until a number of chromosomes are created. Better solutions are displayed during the running process.

4.3.1. The aim of the genetic algorithm

Since CPLEX was time consuming for the first results and endlessly running for the optimized solution, the genetic algorithm was written to try to accelerate the process. During the first tests it was understood that after the first hours of CPLEX optimization the problem was becoming memory consuming. This was slowing down the process and new better solution was hard to be found. For example as shown at Appendix 8.7, for the first scenario after 2 hours we get a solution of objective 2007 and we had to wait for another 30 hours to get the next top solution. Solution with objective 1987 was found 32.5 hours from the beginning of the optimization. This solution remained the best even after 72 hours of optimization.

The size of the problem after the first 2 hours was already 12Gbyte, and 30 hours later, when the next better solution (and final for the whole 72 hours) was found the size was 160GByte (uncompressed).

The genetic algorithm was used with the solution of the solution pool of the first two hours, when the problem is still small. Those solutions were used by the genetic algorithm in order to achieve a better solution. The process was run for all 10 scenarios.

4.4. The data used from CPLEX and Genetic Algorithm

In order to solve the problem, several data were collected from various sources. First of all a list of substations in Central Greece was written up and all the coordinates were gathered. In order to solve the problem the distance between every substation to each other as well as the depots-substations distances needed to be calculated. That was done using Google maps and the more specifically the Distance Matrix service [25]. Code was written in php and run several times in order to get all necessary data. The code is attached at Appendix 8.1.

Moreover, although the distance of the substations from each other was recorded, the useful information and hard to compute otherwise, was the time needed to travel from one substation to the other. This time was also a data mined from Google maps Matrix service. After a quick review of the distances in minutes it was made clear that a refined version of these numbers was needed. The code that “refined” the data and the details can be found at Appendix 8.2.

The above data was combined into the first scenario to be run. With a simple code another 9 pseudorandom scenarios were generated which kept certain aspects unchanged, such as the number of depots, the number of substations, the time to inspect each substation and the magnitude of the distances. The code is included in Appendix 8.8.

4.5. Conclusion

The methods to address the MDVRP problem are explained thoroughly with examples. The full code written for various aspects of the solutions is attached at Appendix. The use of CPLEX in conjunction with genetic algorithm specially designed for MDVRP is presented. This hybrid solution is introduced in order to achieve good results in more logical time windows.

5. Results

5.1. Introduction

The codes proposed at the Chapter 4 were executed for 10 scenarios of data. Each scenario is included at Appendix 8.9. In this Chapter the results of optimization of the two different methods of optimization will be presented. The discussion of the results is included at the last Chapter.

5.2. Steps for solving and comparing the results

Firstly each scenario of data describing distances between substations and depots, was optimized using CPLEX for 24 hours. From each optimization apart from the final solution, the solution pool was mined and chromosomes were produced for the genetic algorithm.

The chromosomes from the first 1.5 hours of running were fed as initial population for the genetic algorithm. The genetic algorithm was run for a target population of 100.000 (time consumed for this execution was less than 5 minutes) and the best routes proposed as well as the objective function were recorded.

The chromosomes from the total 24 hours of CPLEX optimization were also fed to the genetic algorithm. The genetic algorithm was run for a target population of 100.000 and the best routes were noted.

Lastly, CPLEX was allowed to solve the problem for only 5 minutes. All solutions in the solution pool were also fed to the genetic algorithm for optimization. The results were also recorded.

Each genetic optimization was run for more than one time, since much of the procedure is randomly oriented and the total population was restricted to a certain number.

5.3. Memory consumed for CPLEX optimization

The optimization of the problem using CPLEX had a significant impact at the memory consumption after excessive execution of the code.

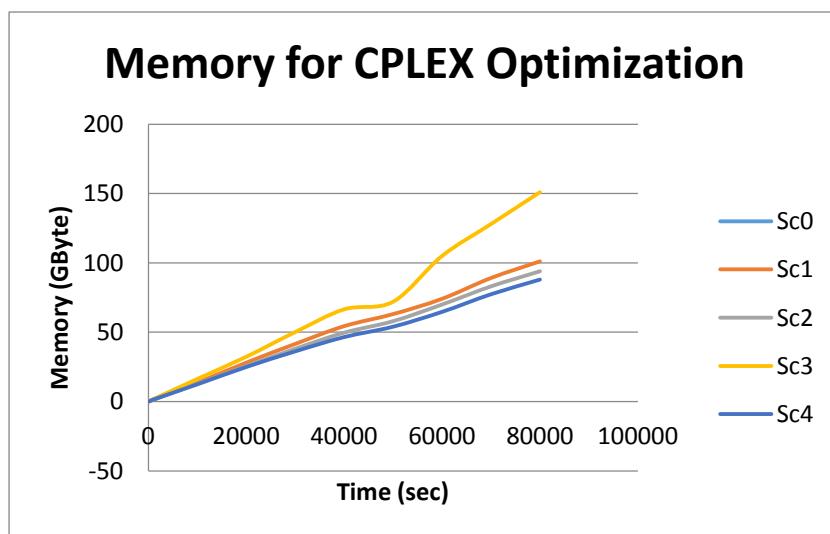

Figure 9: Optimization memory consumption

Memory consumption using CPLEX optimization software was the major crux, as expected. NP-hard problems such as the under study problem will try to use as much space as possible in order to fit all data produced from the “infinite” number of combinations that will be tried out. Figure 9 displays the memory consumption through time for each of the scenarios. As can easily be noted, five hours of optimization enlarge the problem as much as 20Gbyte. The optimization from this point and on was executing with slower pace since the reading and writing to the disk of such an enormous file size of nodes is taking a significant amount of time.

5.4. Gap convergence

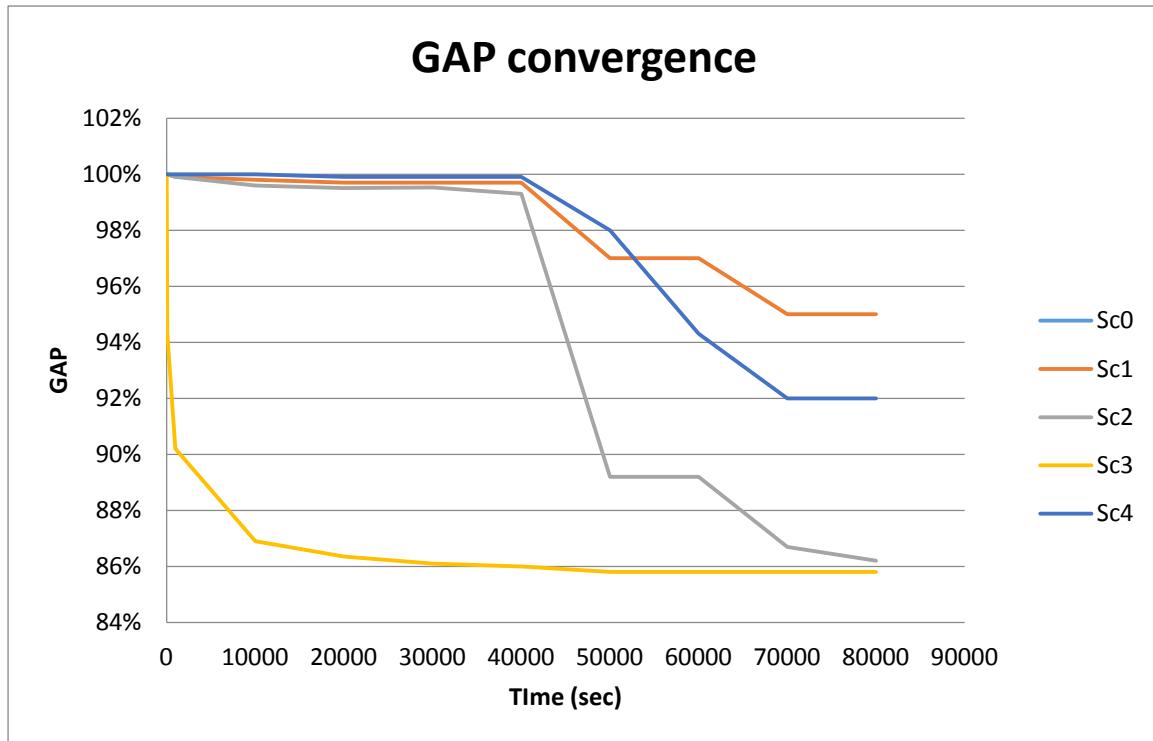

Figure 10: The reduction of Gap during optimization

At Figure 10 the gap convergence is shown against optimization time for all scenarios. The gap is reducing in slow pace and at best it was no less than 85%. Such a gap output can be explained due to the enormous size of the problem for analytic analysis. Please also note that some significant reduction from the 100% initial gap took place only after almost 12 hours of optimization for most of the scenarios.

5.5. Objective convergence

The convergence of the objective for each of the scenarios can also be explained due to the size of the problem. Figure 11 presents the real objective value against optimization time. Significant convergence at the objective value for each of the 10 scenarios is taken place at the first 6 to 10 hours of optimization. After that point little or none improvement of the objective function can be spotted. This is also correlated to the size of the problem as stated above.

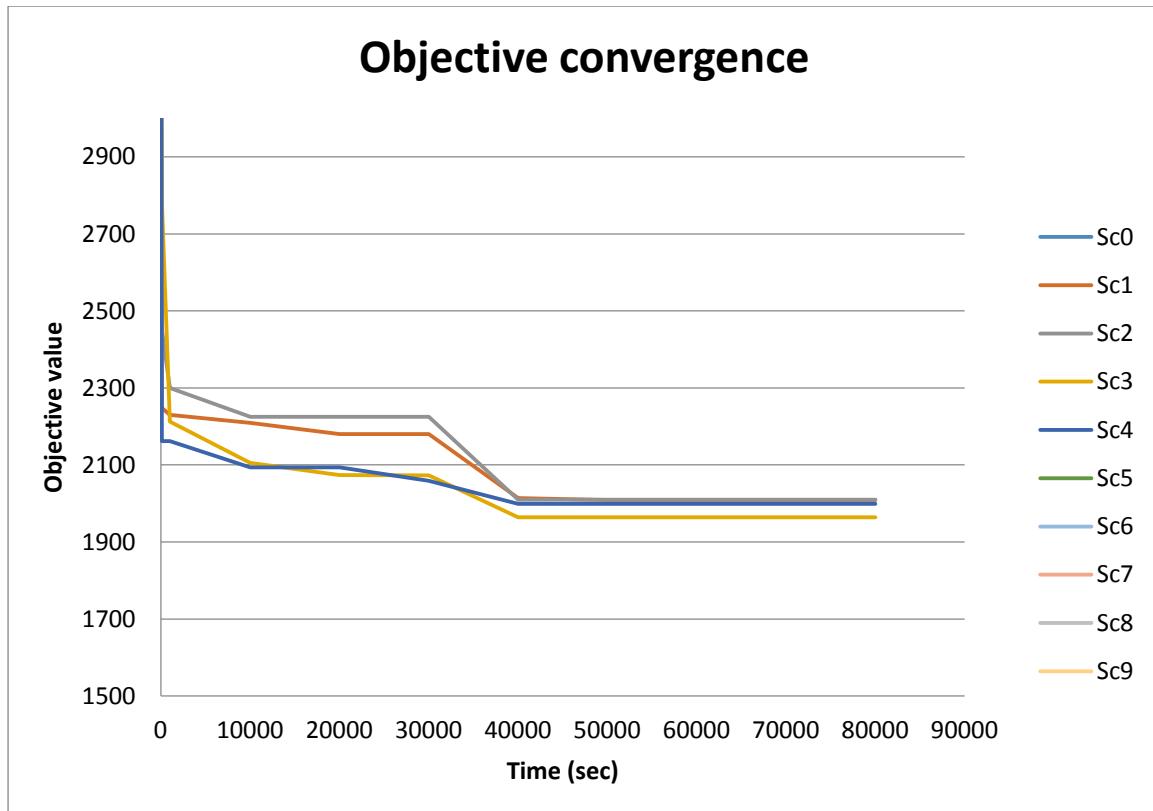

Figure 11: Objective convergence for various scenarios

5.6. Results after 24hours

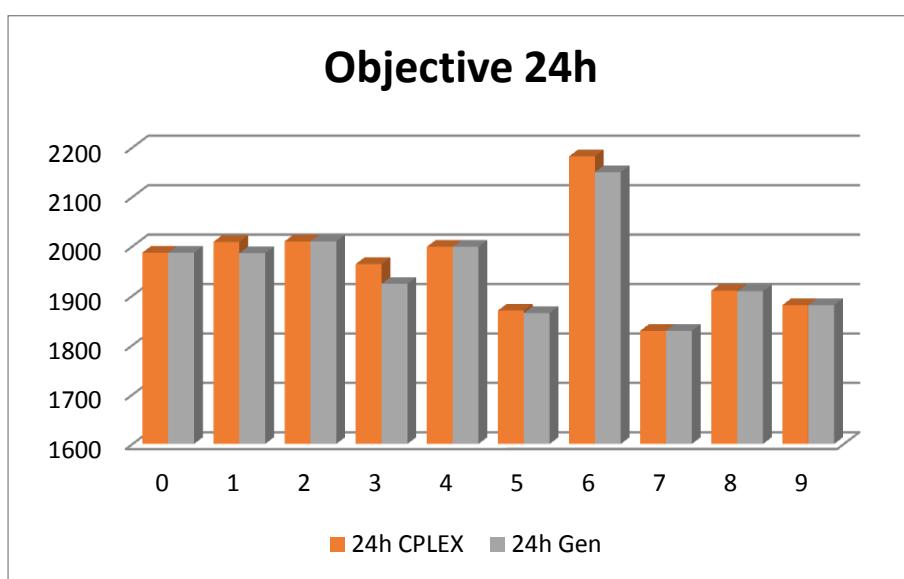

Figure 12: CPLEX and Genetic Algorithm results after 24h of optimization

As pointed above CPLEX optimization after some hours of optimizing is producing better feasible solutions with an significant decelerated pace where the size of the problem is radically enlarged. This behavior is expected to any NP-hard problem. New better feasible solutions are getting

harder to find as time passes by. Therefore there is a need to stop optimizing with CPLEX at some point and try to get better results with another method.

As mentioned above at the beginning CPLEX optimization was run for 24 hours, and then the solutions from the solution pool were mined and fed to the genetic algorithm as initial population for further optimization. As seen on Figure 12 the genetic algorithm managed at almost all different scenarios to produce a slightly better solution than the one produced by CPLEX. The optimization at scenario 1, 3 and 6 was significantly improved using the genetic algorithm while at scenario 0, 4 and 8 failed to produce a better solution.

5.7. Results after 1,5 hours

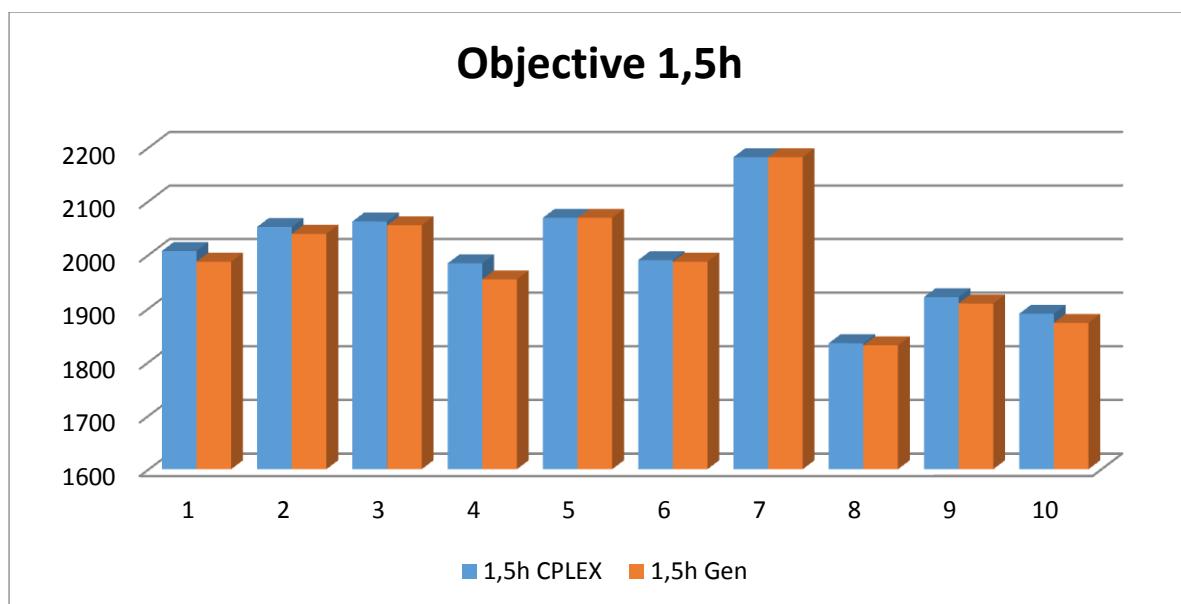

Figure 13: CPLEX and Genetic Algorithm results after 1.5h of optimization

The same procedure was repeated but CPLEX was allowed to run for only 1.5 hours. The solutions from the solution pool were again fed to the genetic algorithm as the initial population and the results as shown at Figure 13 suggest that almost at all scenarios the genetic algorithm managed to improve the optimization significantly. Regarding scenario 5, 6 and 7 CPLEX's solution pool produced only a few results and the initial population was proven not to be adequate for the genetic algorithm. Genetic Algorithm was run for 5 minutes approximately. The feasible solution discovered were in most cases known feasible solution that would be discovered from CPLEX after many hours of optimization. For example, scenarios 4, 9 and 10 genetically optimized to a better feasible solution than the one CPLEX discovered after 24h of running. The combination of 1.5h of CPLEX optimization and the genetic algorithm used, also managed to discover feasible solutions close to the ones produced after 24h of optimization for almost all other scenarios.

5.8. Results after 5 minutes

The above process was repeated one additional time. This time CPLEX optimization was executed for 5 minutes only. Again the solutions from the solution pool were extracted and fed to the genetic algorithm. The resulting optimization of the scenarios is presented at Figure 14

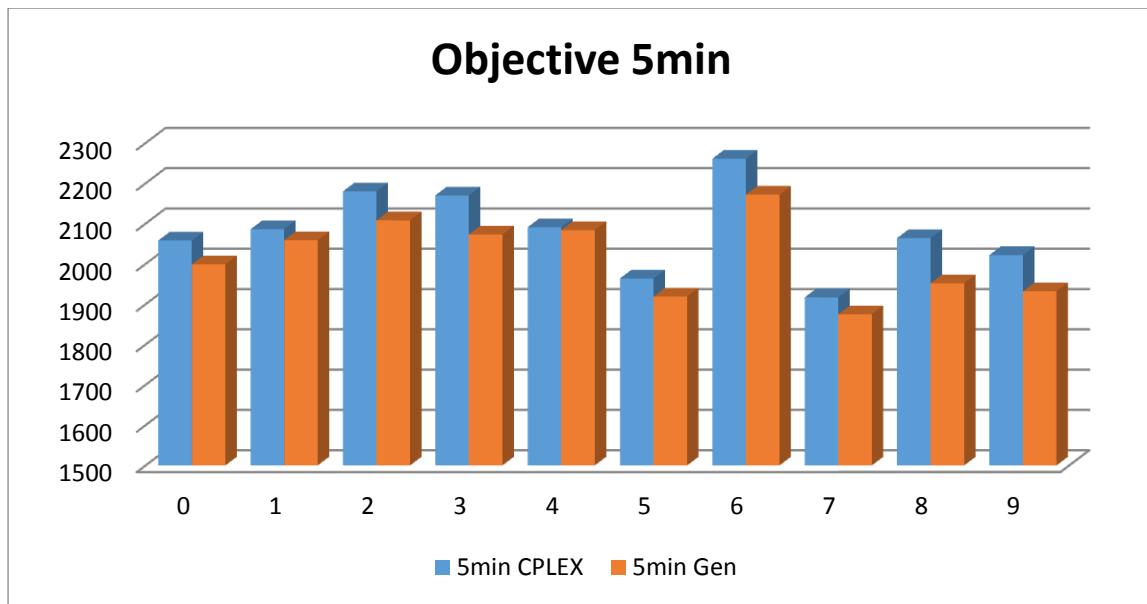

Figure 14: CPLEX and Genetic Algorithm results after 5min of optimization

As it can easily be spotted at each of the scenarios optimization from the genetic algorithm was also significant. The genetic algorithm managed to improve the initial population of solution providing good feasible solutions in short optimization time.

5.9. Comparison of obtained solutions

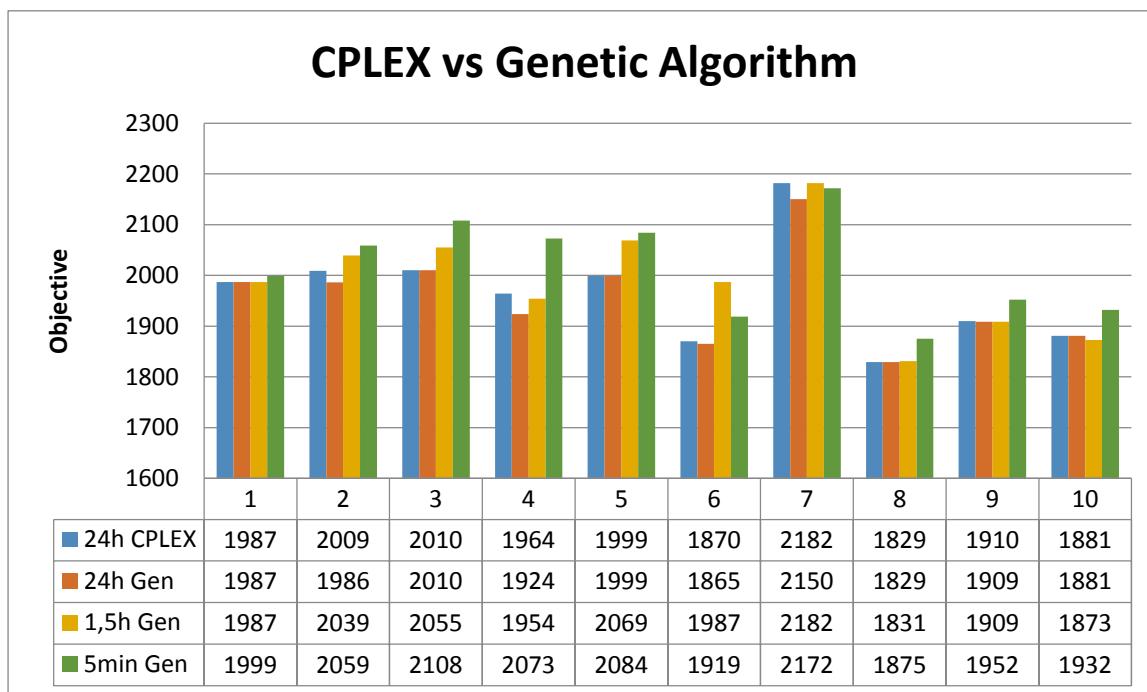

Figure 15: The results for each scenario

Lastly at Figure 15 CPLEX optimization output is compared against the optimization output at the genetic algorithm as executed with three different initial populations. The first bar indicates the best value obtained after 24 hours of CPLEX optimization while the next three are the mixed output of genetic optimization using as initial population the solutions from 24h, 1.5h and 5

minutes running of CPLEX. Even genetic optimization with an uneducated and primitive initial population returned rather promising results.

5.10. Conclusions

The mathematical formulation was run with CPLEX for various scenarios. The solution pool was then accessed and the feasible solutions were fed to the genetic algorithm as initial population. The results were then compared to the results of a 24h CPLEX optimization. The genetic algorithm although primitive in terms of crossover complexity proved to be useful, as it could provide in minutes feasible solutions that could be obtained after hours of CPLEX optimization.

6. Discussion

The vehicle routing problem is and will be for the next years a promising area for research. At this thesis a mathematical model was introduced for the multi depot vehicle routing problem. The solution of this problem will be presented and proposed to the Independent Power Transmission Operator of Greece (IPTO), in order to improve the substation inspection process. As stated in the thesis this inspection is a major part of the stability and readiness of an electric system.

The mathematical formulation of the problem, including the particularities of the routing as proposed by IPTO, were hard coded in C++ and run using CPLEX optimization software.

A genetic algorithm was also built in C++. The code was fed with solutions from CPLEX optimization solution pool, and the code was executed in order to improve the optimization.

It was noted that almost at all scenarios used to test the problem the hybrid genetic algorithm managed to improve the objective value. For instance the feasible solutions of 1,5 hours of optimization were fed as initial population at the genetic algorithm and produced a better feasible solution in a few minutes that in CPLEX would need 20 or more hours of optimization.

Improvements were achieved even when the feasible solution of the scenarios already optimized for 24 hours in CPLEX were fed in genetic algorithm.

The Genetic algorithm used in this thesis used a rather simple crossover and mutation function, but was executed with an initial population of feasible solutions that were mined from CPLEX optimization. This combination proved to be an extremely powerful tool.

Further better results can be achieved if the crossover and mutation functions are enhanced with techniques described in more recent research papers, especially for the MDVRP problem.

Lastly the genetic algorithm could also be enhanced with a more advance educating procedure that would optimize chromosomes in respect to the data of the problem.

8.2. Code to refine the distance matrix produced from google maps

The refinement of the data produced from Google maps was essential since there were several irregularities. For instance the distance (in minutes or km) from substation k to another was different than from s to k. This was introduced due to the way Google maps calculate the distances (actually solving a routing problem). The actual point of a substation and the connected road could be assumed as one way, or two way with double uninterrupted line, were actually it is a small agriculture road. In the first case (assumed from Google maps) the route going or leaving the substation could not be the same were actually it is the same.

The code introduced above eliminates such irregularities choosing the smallest distance (in minutes), and adding a small

```

#include <stdio.h>
#include <string.h>

void main()
{
FILE *fr,*fw,*fn;
int i, j, k=0;
int temp;
int km[29][29];
char name[32][30];

```

```

//OPEN FILES
fr=fopen("apostasiologio.txt", "r");
if (fr==NULL) {
    printf("Cannot open file apostasiologio.txt\nExiting.....\n");
    exit();
}
fn=fopen("substations.txt", "r");
if (fn==NULL) {
    printf("Cannot open file substations.txt\nExiting.....\n");
    exit();
}
fw=fopen("distances.txt", "w+");
if (fr==NULL) {
    printf("Cannot open file distances.txt\nExiting.....\n");
    exit();
}

// READ SUBSTATION NAMES save them to name[i]
for(i=0;i<32;i++){
    fgets(name[i],30,fn);
}

// READ KM save them to km[32][32]
for(i=0;i<29;i++) {
    for(j=0;j<29;j++) {
        fscanf(fr,"%i",&temp);
        km[i][j] = temp;
    }
}

// PRINT EVERYTHING
for(i=0;i<29;i++) {
    for(j=0;j<29;j++) {
        printf("%i ",km[i][j]);
    }
    printf("\n");
}
for(i=0;i<29;i++) {
    printf("%s",name[i]);
}

for(i=0;i<29;i++) {
    for(j=i;j<29;j++) {
        if (km[i][j]>km[j][i]){
            km[i][j]=km[j][i];
            k++;
        }
        if (km[i][j]<km[j][i])
        {
            km[j][i]=km[i][j];
            k++;
        }
    }
}

// PRINT EVERYTHING AFTER THE ALTERATIONS
for(i=0;i<29;i++) {
    for(j=0;j<29;j++) {

8.5. The chromosomes exported from CPLEX optimization

Below there is the representation of the genes as calculated and been saved from the CPLEX code. Each chromosome is a feasible solution. The large numbers (100, 101, 102, 103) are the 4 depots. The small numbers are the substations visited. From instance 100 5 6 100 is a route commencing from depot 0, visiting substation 5, then substation 6 and returning to depot 0.

```
Chromosome 1
100 0 100 100 4 5 6 100 100 1 3 22 2 100 101 9 101 101 8 101 101 7 12 11 101 101 10 101 101 102 13
14 15 102 102 16 17 18 23 102 103 19 20 21 103

Chromosome 2
100 0 100 100 5 6 100 100 1 22 3 2 100 100 4 100 101 10 101 101 101 9 8 7 12 11 101 102 13 14 15
102 102 16 17 18 23 102 103 19 103 103 20 21 103

Chromosome 3
100 0 2 100 100 5 1 100 100 3 4 6 7 100 101 10 101 101 101 13 14 16 101 101 9 8 11 12 101 102 23 15
102 102 17 102 103 21 19 22 103 103 20 18 103

Chromosome 4
100 0 2 7 100 100 1 3 4 6 100 101 10 101 101 13 14 16 101 101 8 11 12 101 101 9 5 101 102 15 19
23 102 102 17 102 103 22 21 103 103 18 20 103

Chromosome 5
100 0 4 2 100 100 6 7 17 100 100 1 3 100 101 10 8 101 101 13 14 16 101 101 101 9 12 5 101 102 15 19
23 102 103 21 22 103 103 11 18 20 103
```

Best solution of this scenario after 72 hours was 1987 objective value							

8.8. Generation of scenarios

Code that produces pseudorandom distance matrices.

```
#include <stdio.h>
#include <string.h>
#include <time.h>
#include <stdlib.h>
#include <math.h>

void main()
{
FILE *fr,*fw,*fn;
int i, j, k=0,u ;
int temp;
int km[29][29];
```

```

char name[32][30];

srand( (unsigned)time( NULL ) );

//OPEN FILES
fr=fopen("apostasiologio.txt", "r");
if (fr==NULL) {
    printf("Cannot open file apostasiologio.txt\nExiting.....\n");
    exit(1);
}
fn=fopen("substations.txt", "r");
if (fn==NULL) {
    printf("Cannot open file substations.txt\nExiting.....\n");
    exit(1);
}
fw=fopen("senariol.txt", "w+");
if (fr==NULL) {
    printf("Cannot open file distances.txt\nExiting.....\n");
    exit(1);
}

// READ SUBSTATION NAMES save them to name[i]
for(i=0;i<32;i++){
    fgets(name[i],30,fn);
}

// READ KM save them to km[32][32]
for(i=0;i<29;i++){
    for(j=0;j<29;j++) {
        fscanf(fr,"%i",&temp);
        km[i][j] = temp;
    }
}

// PRINT EVERYTHING
for(i=0;i<29;i++){
    for(j=0;j<29;j++) {
        printf("%i ",km[i][j]);
    }
    printf("\n");
}
for(i=0;i<29;i++) {
    printf("%s",name[i]);
}

for (i=0;i<29;i++) {
    for (j=0;j<29;j++) {
        if (i!=j) u=rand()%100-25; else u=0;
        km[i][j]=km[i][j]+u;
    }
}

for(i=0;i<29;i++) {
    for(j=i;j<29;j++) {
        if (km[i][j]>km[j][i]) {
            km[i][j]=km[j][i];
            k++;
        }
        if (km[i][j]<km[j][i])
        {
            km[j][i]=km[i][j];
            k++;
        }
    }
}

```

```

printf("/n/n ALLAGES=%i \n", k);

for(i=0;i<29;i++){
    for(j=0;j<29;j++){
        fprintf(fw,"%i\t",abs(km[i][j]));
        printf("%4i ",abs(km[i][j]));
    }
    fprintf(fw,"\n");
    printf("\n");
}
}

```

8.9. Scenarios

Apart from the real data used (scenario 0) the following data were fed as distances in minutes to the algorithms:

Scenario 1
